The Higgs and beyond

Theoretical particle physics
at Carleton University

Heather Logan
Particle physics studies the structure of matter on the smallest scales that we can probe experimentally.

Size of atom = 1/100-million cm
Size of nucleus = 1/100,000 of atom

Theoretical particle physics interprets the experimental results in a coherent mathematical framework.

- Make detailed predictions based on current understanding
  - “Standard Model” of particle physics: works very well so far!
  - Detailed understanding of “backgrounds”: allows experiments to know when they’ve found something new.

- Develop new ideas (theories) to address observational or theoretical problems
  - There are holes in our understanding: we know the Standard Model can’t be the whole story.

- Figure out predictions of the new theories so they can be tested by experiments
  - This is the only way to tell whether a new theory is right or wrong!
  - Theory input helps community figure out what experiments to build.
Is There a Light Scalar Boson?

L. Resnick, M. K. Sundaresan, and P. J. S. Watson

Department of Physics, Carleton University, Ottawa, Canada
(Received 28 July 1972; revised manuscript received 2 January 1973)

In view of recent theoretical interest in the possibility of a light scalar boson $\phi$ we discuss some of its properties and possible methods for detecting it. Cross sections for its production are typically $10^{-8}$ of competing processes, with the possible exception of $0^+ - 0^+$ transitions in nuclei. We also give a

Higgs mechanism theorized 1964, incorporated into Standard Model 1967;
Standard Model became respectable 1971 with development of renormalization;

The Big Questions

Is the Higgs boson really responsible for other particles’ masses?

What keeps the Higgs boson from getting a huge mass from quantum effects?

What is the dark matter?

What happened to all the antimatter?

Why are neutrinos so much lighter than all the other particles?

Why are there so many quarks and leptons, with such different masses?
The Big Questions Carleton people are working on

Is the Higgs boson really responsible for other particles’ masses?

What keeps the Higgs boson from getting a huge mass from quantum effects?

What is the dark matter?

What happened to all the antimatter?

Why are neutrinos so much lighter than all the other particles?

Why are there so many quarks and leptons, with such different masses?
What keeps the Higgs boson from getting a huge mass from quantum effects?

Properties of particles get “screened” at very short distances by virtual particles (a quantum-mechanics effect; they kind of tunnel into existence).

Charge of electron is a little stronger if you measure it really close up. (within less than 1/100 of size of atom)

Calculation of this effect uses language of loop diagrams.

Masses of particles also get a quantum correction: mass that we measure is not the “original input” to the theory.
What keeps the Higgs boson from getting a huge mass from quantum effects?

For most particles, these quantum corrections to charges and masses are pretty small, no big deal.

For the Higgs boson, these quantum corrections are enormous. The Higgs is special: the only fundamental spin-zero particle we know of.

Physical mass = “original input” + quantum correction

Quantum correction is \( \sim 30 \) orders of magnitude bigger than the physical mass! Second-worst prediction in all particle physics.

Has to be cancelled by “original input”: a very implausible coincidence.
What keeps the Higgs boson from getting a huge mass from quantum effects?

To solve this problem we need a new theory with a physical mechanism to get rid of the enormous quantum correction.

Physical mass =  
“original input” + quantum correction  
+ new quantum correction

A good new theory will give us  
Physical mass ≈ “original input” 
≈ quantum correction + new quantum correction

The new quantum correction comes from new particles.  
Not just random new particles: their properties need to be just right to fix the Higgs mass problem. New physical principles → very specific expt. predictions.

Research Works March 2013
What keeps the Higgs boson from getting a huge mass from quantum effects?

Some candidates for the new theory:

* **Supersymmetry**

* Bonus: could explain dark matter!

* **Little Higgs**

* **Composite Higgs**

All these predict new particles with very specific properties.
- How to search for them at the LHC and other colliders?
- How to measure their properties and test whether they solve the Higgs mass problem?
